**Abstract** A series of Fe/MnO catalysts (Fe/Mn=1/4) modified with K, Cu, Co, Pd and Rh for CO hydrogenation were prepared to obtain a higher selectivity to low molecular weight olefins. The catalytic behavior of these catalysts was studied at temperature of 543 K, under pressure of 1.1 MPa and with GHSV=215 h<sup>-1</sup>. It was found that the activity of CO hydrogenation increased over the modified Fe/MnO catalysts except K-Fe/MnO. An increase in the selectivity to C<sub>2</sub><sup>=</sup>~C<sub>4</sub><sup>=</sup> was also observed over Cu and Co modified catalysts. Influences of coke formation on the catalytic activities of catalysts were investigated. A relationship between the activity of CO hydrogenation and coke deposits was suggested.

**Keywords** F-T synthesis, modified Fe/Mn oxide, coke deposit, olefin selectivity

## Introduction

It has been reported that Fe/MnO is a selective catalyst for the production of low molecular olefins in the F-T synthesis<sup>[1]</sup>. Some researchers have investigated the function of Mn as a promoter. The effect of manganese oxide as a catalytic component has been observed with elements other than Fe, in particular, similar effects have been observed for Co-Mn<sup>[2]</sup> and Ru-Mn<sup>[3]</sup> catalysts. It has been suggested that there is a considerable interaction between iron and manganese oxide, and a solid solution is formed in the catalyst system. Also, it could be supposed that the selectivity to C<sub>2</sub><sup>=</sup>~C<sub>4</sub><sup>=</sup> may be further

increased by proper modification of Fe/MnO. The "proper metal ions" means that they can modify the catalyst surface property and benefit the reduction of  $\text{Fe}^{3+}$  to  $\text{Fe}^0$ , because  $\text{Fe}^0$  has been thought as an active component for CO hydrogenation<sup>[4]</sup>. In addition, the product distribution can be changed by using Rh- or Pd-catalyst to produce more methanol or alcohols<sup>[5]</sup>. In our work, efforts have been made to increase the  $\text{C}_2^=\sim\text{C}_4^=$  selectivity by modifying the Fe/MnO catalysts with different metal promoters. It has been found that there was an activity lost on some catalysts and a certain amount of coke deposits on the surface of catalysts as well as in the bulk. In this paper, we try to correlate both the coke deposition and the catalyst activity with promoter properties.

## Experimental

### Catalyst preparation and catalytic reaction

The manganese rich Fe/Mn oxide catalyst (Fe/Mn=1/4) was prepared by continuous co-precipitation of Fe-, Mn-nitrates and ammonia solutions at 70°C and pH=9.2, followed by drying at 120°C and calcination at 500°C for 24 h in Ar in order to forbid the formation of metal carbonates. 1%K, 1%Cu, 1%Co, 1%Pd, 1%Rh and 0.1%Co (in mol%) were loaded respectively by impregnating the calcined Fe/Mn oxide precursor with their nitrates solution followed by treating under the same conditions stated above. The exact compositions of the catalysts were determined by atom adsorption spectrometer. The reactant gas was composed of 30%(vol.)CO, 60%(vol.)H<sub>2</sub> and 10%(vol.)Ar. It was contained in an aluminum cylinder to minimize carbonyl impurity. A tubular stainless-steel reactor (103 mm in length and 12 mm in diameter) was used and charged with 3 g of catalyst. The prepared catalysts were pelleted into cylinder form (3 mm × 3 mm). Before the syngas was charged to the reactor, the catalyst was reduced with hydrogen at 400°C for 12 h. The reactions were mainly performed at 543 K, GHSV=215 h<sup>-1</sup> and  $P=1.1$  MPa. The reaction time was 48 h for most samples. The effluent was directed to an on-line gas chromatograph. The products were analyzed by a Carle AGC 111 with four columns (DC 200/500, Carbowax 1540, Porapak N and molecular sieve 13X). The liquid effluent was condensed in two condensers, which were held at 100°C and cold water respectively. After reaction, the liquid was collected in two condensers and then mixed. The oil phase and water phase were separated and then were weighted. The analysis of products was carried out on a Perkin Elmer Sigma 2B with an OV 101 column.

### Catalyst characterization

The catalysts were characterized with X-ray photoelectron spectroscopy in every treatment step, *i.e.* calcination, reduction and passivation, *in situ* reduction as well as

reaction. The XPS studies were performed with a spectrometer of Leybold-Heraeus LHS/10, Al-K $\alpha$ =1486.6 eV in a vacuum system of 0.1 Pa. For XPS studies, the catalysts were calcined in the presence of Ar at 500°C at first. After that, they were reduced with H<sub>2</sub> (65 mL/min) at 400°C for 24 h in another apparatus. Then the catalyst was passivated with a mixed gas composed of 2%(vol.) O<sub>2</sub> and 98%(vol.) N<sub>2</sub> at room temperature for 2 h. The sample to be tested was transferred into the chamber of the XPS spectrometer. Before analysis, it must be *in situ* reduced at 400°C for 1 h.

The bulk coke content was determined by measuring the CO<sub>2</sub> amount which was emitted from the sample burning.

## Results and discussion

### Catalyst activity in CO hydrogenation

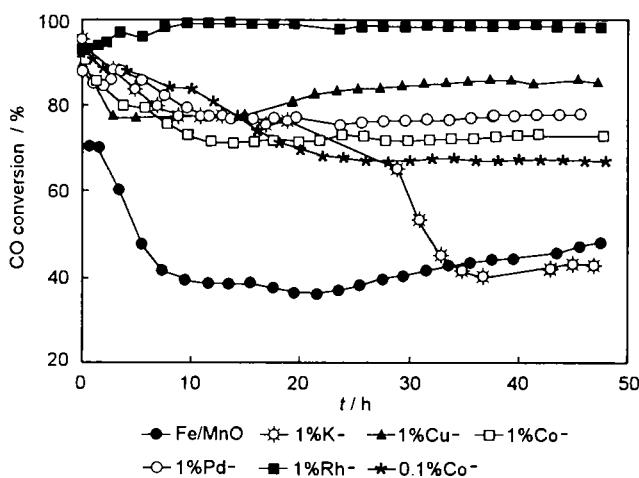

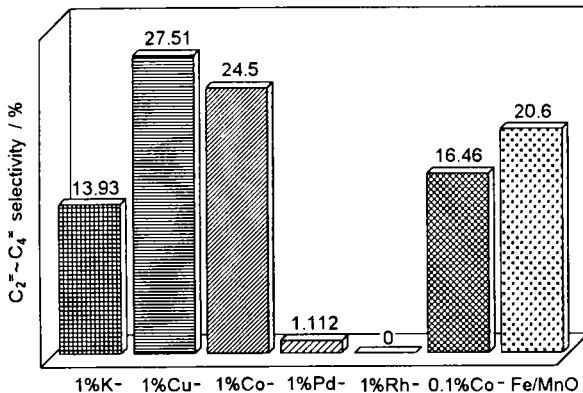

Fig.1 Variation of CO conversion with reaction time

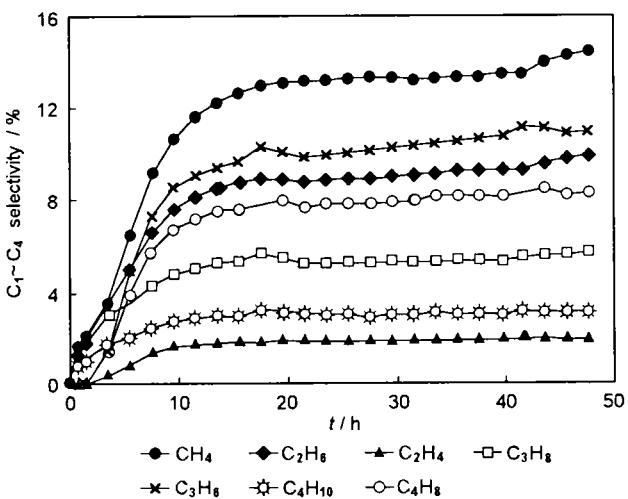

Fig.1 shows the conversion of CO (based on the CO amount in inlet and outlet) as a function of reaction time over different modified catalysts. The results indicated that the conversion of CO was significantly enhanced through the metal modification with Cu, Co, Pd and Rh. A decrease in CO conversion from about 70% at the beginning to 40% after 10 h was observed over the unpromoted Fe/MnO catalyst. A light increase of CO conversion was thereafter observed with reaction time. The K-containing sample also showed a change in activity. There was an obvious conversion fall from about 80% to 40% during the reaction time of 20~35 h, then the conversion tended to be stable. The 1%Rh promoted catalyst had the highest activity with almost 100% of CO conversion,

while other samples had the activity level of 75-85%.

#### *Effect of metal modification on the selectivity to different products*

**Fig.2** Selectivity to  $C_2= \sim C_4=$  olefins at 543 K,  
GHSV=215  $h^{-1}$  and  $P=1.1$  MPa

**Fig.3** Selectivity to  $C_1 \sim C_4$  hydrocarbons on Fe/MnO  
at 543 K, GHSV=215  $h^{-1}$  and  $P=1.1$  MPa

Fig.2 shows the selectivity to  $C_2= \sim C_4=$  over different catalysts. A significant amount of  $C_2= \sim C_4=$  was obtained on the Cu and Co modified catalysts (up to 28% and 25%, respectively, CO<sub>2</sub>-free selectivity). Nevertheless, in contrast to the selectivity to  $C_2= \sim C_4=$  over the Cu and Co modified catalysts, the Pd and Rh had a negative effect on the activity of Fe/MnO catalyst to produce  $C_2= \sim C_4=$  olefins, only 1% olefins over 1%Pd- was

produced and almost nothing was found over 1%Rh-Fe/MnO. This result is easy to be understood because of their superior hydrogenating function. It can be seen from Figs.3 and 4 that the unmodified Fe/MnO was a good catalyst for the production of short chain olefins (selectivity to  $C_2 \sim C_4$  is 20.6%), nevertheless, compared with 1%Cu-Fe/MnO, on which more olefins were produced, this unmodified catalyst showed lower selectivity. Over 1%Cu-Fe/MnO, the selectivities to  $C_3 =$  and  $C_4 =$  were higher than that of their aliphatic hydrocarbon form (see Figs.3 and 4).

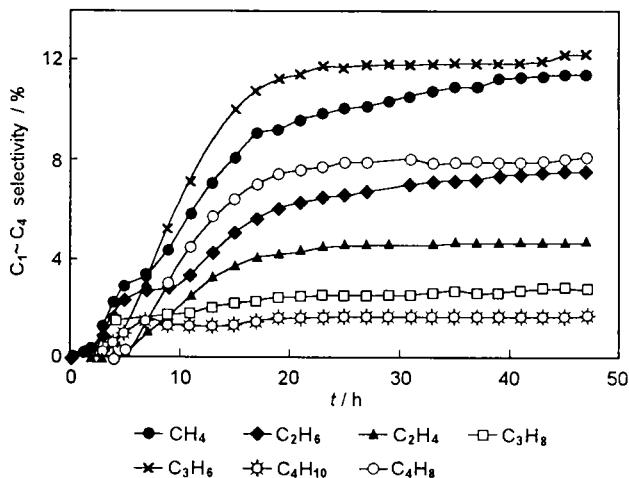

Fig.4 Selectivity to  $C_1 \sim C_4$  hydrocarbons on 1%Cu-Fe/MnO at 543 K, GHSV=215  $h^{-1}$  and  $P=1.1$  MPa

#### Effect of different promoters on the coke formation

The coke formation over different modified Fe/MnO catalysts is shown in Table 1. As we can see that a strong enrichment of coke was observed both at the surface and in the bulk of the K-containing catalyst.

The surface content of coke was measured by XPS. It can be also determined if the surface C-species is in the form of graphite or  $\text{C}=\text{O}/\text{C}-\text{C}=\text{O}$  or  $\text{C}-\text{O}$ . There were four steps of measurement. The first step was the calcination in Ar (see "calcined"). Then, the calcined catalyst sample was reduced with  $\text{H}_2$  and passivated with  $\text{O}_2$  to form a thin layer of oxide to inhibit the further oxidation (see "reduced and passivated"). In the third step, the passivated samples were transferred into the chamber of the XPS spectrometer and were *in situ* reduced at 400°C for 1 h before measurement (see "*in situ* reduced"). After reaction, the catalysts were detected by XPS. The total amount of bulk C was measured by the amount of  $\text{CO}_2$  from burning of catalyst.

**Table 1** Coke formation over different modified Fe/MnO catalysts

Catalyst	Catalyst treatment	Surface		Bulk	Attribute of C-species

\* the coke deposited could not be separated from the sample holder for too small amount.

\*\* too small amount

As a result, a strong enrichment of coke was observed both on the surface and in the bulk of the K-containing catalyst after reaction, showing a carbon content of 66% on the surface, while only about 20~25% carbon contents were obtained over the other catalysts. In addition, the bulk of 1%K-Fe/MnO catalyst contained 12 atom% carbon, which is higher than that of the K-free catalysts (carbon content lower than 4%). That is to say, potassium had a very strong influence on the carbon deposition during synthesis. If we

compare 1%K-Fe/MnO with other catalysts (see Fig.1), we can see a declined trend of activity.

After calcination, there was no more than 10% coke found on the surface other than 1%Co- and 0.1%Co-Fe/MnO. When the catalysts were *in situ* reduced in the reactor, the coke deposited mainly exists in graphite C and the amount of deposits on the surface reached a minimum. The relationship between the conversion of CO and the carbon content on different modified catalysts after reaction is shown in Fig.5. It can be seen that there is a parallel relation between the conversion of CO and the coke deposits on the surface (in unit of  $1/C\text{-atom}\%\times 10$ ). It can be deduced that the activity in the quasi-stable period is dependent on the amount of coke deposited on the catalyst surface. Nevertheless, it does not mean that the conversion level at the beginning of the reaction is associated with the coke deposits, it is related to the content of the metallic characters of Fe carbide<sup>[6]</sup>.

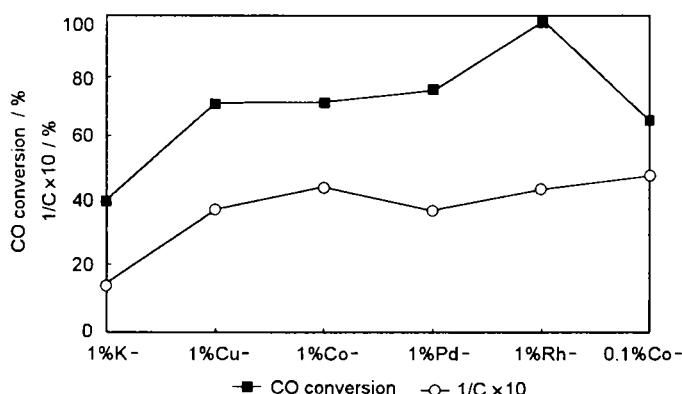

Fig.5 CO conversion and reciprocal( $\times 10$ ) of surface coke content over different modified Fe/MnO catalysts

## Conclusions

1. Cu, Co, Pd and Rh modification could enhance the CO conversion over Fe/MnO. The Cu, Co modified Fe/MnO catalysts give higher selectivities to  $C_2^=$ ~ $C_4^=$  than Fe/MnO does.
2.  $C_3^=$  and  $C_4^=$  selectivities were higher than that of their aliphatic hydrocarbon form over Cu-Fe/MnO in comparison with the unpromoted Fe/MnO.
3. The activity in the quasi-stable period is dependent on the amount of coke deposited on the catalyst surface after reaction.
